Key words: Malignancy phenotype. Common variable immunodeficiency. Non-Hodgkin lymphoma. Gastric adenocarcinoma.

Palabras clave: Fenotipo maligno. Inmunodeficiencia común variable. Limfoma no-Hodgkin. Adenocarcinoma gástrico.

Common variable immunodeficiency (CVID) is a heterogeneous group of disorders, characterized by hypogammaglobulinemia and defective specific antibody production [1,2]. Although the hallmark of the disease is frequent infections, primarily affecting the respiratory and gastrointestinal tracts, the clinical spectrum of CVID is vast and includes malignancy [3]. The incidence of malignancy in CVID is around 11% to 13% and usually occurs during the fifth or sixth decade of life [4]. The most common sites of involvement are the gastrointestinal tract and the lymphoid tissues. In the following study, we will discuss our experience with different cancers observed in CVID patients.

Ten percent of the clinical phenotypes observed in 93 patients diagnosed with CVID at the Children's Medical Center Hospital (Pediatrics Center of Excellence in Tehran, Iran) were malignant phenotypes. The diagnosis of non-Hodgkin lymphoma was based on the American College of Radiology Appropriateness Criteria while that of gastric adenocarcinoma was based on pathologic findings of gastric epithelial neoplasia. Four male and 3 female patients, with a median age of 16 years (range, 12-59 years), had cancer; there were 4 cases of non-Hodgkin lymphoma and 3 cases of gastric adenocarcinoma. The demographic data and laboratory findings for these 7 patients are presented in the Table. The mean (SD) age at onset of symptoms was 7 (1.7) years and the age at diagnosis was 13 (2.4) years; these ages were significantly higher than those recorded in all Iranian CVID databases (P<.001). Surprisingly, all the patients with lymphoma had childhood onset, while those with gastric cancer were in their fourth decade of life when the cancer was diagnosed. Although no population-based epidemiological studies have analyzed demographics or epidemiological indices for malignancy in patients with CVID, the incidence of all types of cancer has been estimated to be 1.8 to 13 times higher than in the general population [5]. According to our findings, the incidence of cancer in Iranian CVID patients is 10%, which is 2.5 times higher than the risk of cancer in the general population [6]. The increased prevalence of cancer in immunodeficiency may be explained by an increased risk of immune dysregulation, increased susceptibility to an infectious agent involved in carcinogenesis, or chromosomal instability due to the nature of the disease [7]. Moreover, lower total and $CD4^+$ T cells and natural killer cells in terms of number and function have been strongly associated with risk for subsequent development of malignancy in CVID patients [8]. In our study, the most common forms of cancer were non-Hodgkin lymphoma and gastric adenocarcinoma. In previous studies, patients with CVID, and particularly female patients, have been found to have an 15.2- to 438-fold increased risk of developing non-Hodgkin lymphoma compared to the general population [5,7,9]. In another study of 120 CVID patients, 46% had non-Hodgkin lymphoma, while 7% had Hodgkin lymphoma [10]. Most of the patients in our study developed

Table. Demographics and Disease Characteristics in 93 Iranian Patients With Common Variable Immunodeficiency (CVID)

lymphoma at an early age. Lymphoma as a complication of CVID is well known and usually consists of nodal lymphoma, non-Hodgkin lymphoma, or B-cell lymphoma, which present in female patients an average of 9 years after diagnosis of CVID; the median age at diagnosis is 23 years and the lymphoma is normally found in association with T-cell defects [3,9]. In addition, the stage of lymphoma in young CVID patients is low grade B-cell tumors without bone marrow involvement. The observed prevalence of lymphoma may be due to Epstein-Barr virus (EBV) infection or reactivation of weakness of the immune system. However, EBV is not detectable in most patients. Furthermore, CVID patients with systemic and local granulomatosis are more susceptible to developing lymphoma; the diseases may have the same origin, ie, immune dysregulation and infection with B-cell lymphotropic human herpes virus type 8 (HHV8) [7].

Patients with CVID have a 10- to 47-fold increased risk of gastric adenocarcinoma [5,7,9]. In one study, 16% of 120 patients with CVID in the Immunodeficiency Cancer Registry had this type of cancer [10]. In fact, our study suggests that elderly patients may be more vulnerable to gastric adenocarcinoma and that symptoms tend to present at an advanced stage of disease, with catastrophic clinical consequences. Furthermore, achlorhydria and suppression or lack of secretory immunoglobulin (Ig) A, which compromise defense against *Helicobacter pylori* infection in CVID patients, suggest a relative cause for gastric cancer, which is markedly increased in these patients. In our series, there was a female patient with breast cancer who had a large number of chromosome aberrations, despite receiving low radiation doses. Accordingly, it is possible that the immune impairment in CVID may have a role in the development of breast cancer by increasing susceptibility to infection with the mouse-mammary-tumor-virus-env-gene-like 660 base pair sequence, which has been found in 38% of human breast cancers. CVID patients should thus receive appropriate cancer surveillance including frequent imaging. Two patients in our study had some evidence of radiosensitivity before they developed cancer. As a matter of fact, these patients had statistically significant results for chromatid gaps, total number of aberrations per cell at a radiation dose of 0.5 Gy, and for all types of aberrations except chromosome breaks at a radiation dose of 1 Gy. There is controversy regarding the effects of the use of multiple diagnostic tools (eg, chest radiographs, computed tomography scans, mammograms, and barium swallow and enema procedure) to screen for malignancy in CVID patients, as it has been suggested that this might actually increase risk. Unnecessary radiographic diagnostic tests should thus be avoided or replaced by alternative tests, and minimum radiation doses should be ensured in all cases. There is also controversy surrounding the use of radiotherapy in CVID patients with cancer. The toxic effects of radiation in CVID patients, however, are dose-dependent and it would be interesting to establish a threshold for radiation-induced aberrations in CVID patients as this would help to ensure the use of safe doses for diagnostic and therapeutic procedures.

Finally, 2 of the 7 patients in our series died; the 15-year survival rate was 72%, which is significantly lower than that for a reference CVID group without cancer matched for age, race, and sex (82%) (P<.001) [1].

Importance of Controlled Sting Challenge and Component-Resolved Diagnosis in the Success of Venom Immunotherapy

G Dalmau Duch,[1] V Gázquez García,[1] P Gaig Jané,[1] A Galán Nieto,[2] RI Monsalve Clemente[2]
[1]*Allergology Section, Hospital Universitari de Tarragona Joan XXIII, Institut d'Investigació Sanitària Pere Virgili, Tarragona, Spain*
[2]*ALK-Abelló, S.A., Madrid, Spain*

Key words: Component-resolved diagnosis. Cross-reactivity. *Polistes dominulus*. Sting challenge.

Palabras clave: Diagnóstico por componentes. Reactividad cruzada. *Polistes dominulus*. Repicadura.

Polistes dominulus and *Polistes gallicus* are very common species of wasps in many European countries, especially in the Mediterranean area [1]. Traditionally, allergies to these species were diagnosed and treated using the American *Polistes* species venom mixture (APmix). However, recent papers have shown that cross-reactivity between American and European species is quite limited [2] and, for this reason, the use of European species such as *P dominulus* improves diagnostic capacity and the success of venom immunotherapy (VIT) in patients who experience an anaphylactic reaction after being stung by these wasps [3].

We report the case of a 58-year-old woman who experienced 2 anaphylactic reactions after being stung by a wasp in 2 consecutive years. In the summer of 2005, she experienced a grade IV anaphylactic reaction [4] after a wasp sting (the insect was identified by the patient), and a similar episode occurred the following summer. After this second episode, the patient went to the hospital for allergy testing. Intradermal tests were negative for *Apis meliifera* and *Vespula* species and positive for *Polistes* species (0.001 μg/mL). Specific immunoglobulin (sIg) E was negative for *Apis meliifera*, mildly positive for *Vespula* species (1.38 kU/L), and clearly positive for *Polistes* species (19 kU/L). Based on these results, VIT was immediately initiated with APmix. The maintenance dose of 100 μg was achieved without problems. After 6 months of treatment, the patient returned to the hospital for assessment by a controlled sting challenge. According to our protocol, serum tryptase and total and sIgE were measured before the challenge. The results were 6.94 μg/L for tryptase, 23.3 IU/mL for total IgE, and 0.01 kU/L for *Apis meliifera*, 0.21 kU/L for *Vespula* species, and 5.14 kU/L for *Polistes* species. A few minutes after the sting challenge, the patient experienced a grade IV anaphylactic reaction, which was treated with adrenaline. We repeated the serum tests (samples taken after 90-120 minutes) and obtained the following results: 17.2 μg/L for tryptase, 21.6 IU/mL for total IgE, and 0.02 kU/L for *Apis mellifera*, 0.20 kU/L for *Vespula* species, and 4.72 kU/L for *Polistes* species. VIT was discontinued immediately and sIgE to the main allergenic components (phospholipases and antigen 5s from *Vespula vulgaris* and *P dominulus*) were measured with the ADVIA-Centaur platform [5]. The results were negative for all allergens but the phospholipases Ves v 1 (0.54 kU/L) and Pol d 1 (35.79 kU/L). With these results, we decided to initiate a second cycle of VIT with a *P dominulus* extract (Pharmalgen; ALK-Abelló, S.A.) in October 2007. Six months after initiating this new phase of treatment, we repeated the sting challenge at the hospital. The patient experienced just a local reaction. The sIgE to Pol d 1 decreased to 12.96 kU/L (and 0.23 for the cross-reactive Ves v 1). In addition, a Pol d 1 sIgE inhibition assay was performed with 3 extracts (Figure): the APmix sample used in the first VIT, an APmix extract, and a *P dominulus* extract (both at the same concentration and preincubated with the biotinylated Pol d 1). Inhibition of Pol d 1 sIgE was only achieved with the *P dominulus* extract, demonstrating its specificity. After inhibition, sIgE was 9.2 kU/L. There was no inhibition whatsoever with the other extracts (Figure), demonstrating that only the *P dominulus* extract contained allergenic components. This species-specific composition must be the reason for the anaphylactic reaction that occurred after the first sting challenge with *P dominulus*, since the initial VIT had been performed using APmix. Our results indicate that in patients allergic to *Polistes*, *P dominulus* must be considered as mandatory for diagnosis as well as a first-line treatment option for VIT. Controlled sting challenge and component-resolved diagnosis are essential tools in the diagnosis and control of these patients.

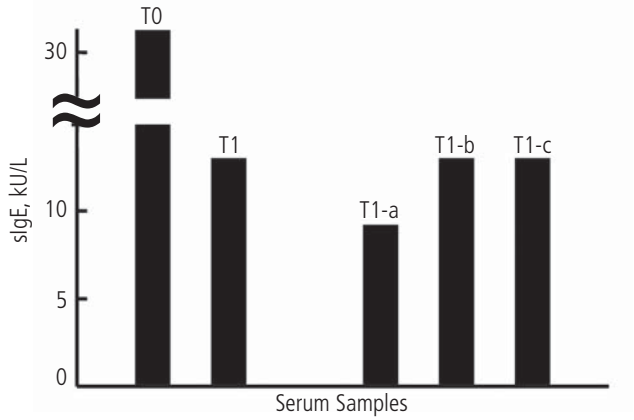

Figure. Pol d 1 specific immunoglobulin (sIg) E values measured with ADVIA-Centaur, after the first controlled sting challenge (T0), after venom immunotherapy (VIT) with *P dominulus* (T1), and after inhibition of the latter serum sample with identical concentrations of *P dominulus* extract (T1-a), APmix extract (T1-b), and the APmix used in the initial VIT (T1-c).

Differences Between General Practitioners and Allergists in Treating Moderate to Severe Persistent Rhinitis

M Branco Ferreira
Immunoallergology Department, Hospital de Santa Maria, Faculty of Medicine, University of Lisbon, Lisbon, Portugal

Key words: Allergic rhinitis. ARIA. General Practitioners. Immunoallergologists. Treatment.

Palabras clave: Rinitis alérgica. ARIA. Médicos Generalistas. Inmunoalergólogos. Tratamiento.

Adherence to the Allergic Rhinitis and its Impact on Asthma (ARIA) guidelines on the treatment of allergic rhinitis is generally considered to be poor among general practitioners (GPs), particularly regarding the prescription of nasal corticosteroids [1]. A recent study has even suggested frequent nonadherence to international guidelines among specialists, based on the answers to a questionnaire featuring 4 clinical case scenarios [2].

We evaluated the treatment choices of allergy specialists and GPs for allergic rhinitis using 2 clinical case scenarios (vignettes) in the form of a written questionnaire. The vignettes dealt with the treatment of moderate to severe persistent allergic rhinitis in adult patients without bronchial symptoms. Case 1 had predominant obstructive symptoms while case 2 had predominant histamine-induced symptoms (sneezing, itching, and rhinorrhea). The questionnaire was given to 467 physicians (397 GPs and 70 allergy specialists) who volunteered to participate in this study. The physicians all considered that they were used to treating allergic rhinitis and were familiar with the different treatment options available.

For each clinical vignette, the physicians were asked the following question "What would you prescribe to this patient on his/her first visit?". They were able to choose from a combination of 5 different drug classes as well as different doses and regimens. Specific immunotherapy was not an option.

The Table shows the drugs chosen for each case by the GPs and the allergy specialists. While maintenance daily nasal corticosteroids were prescribed by both groups for the 2 cases of moderate to severe persistent rhinitis, they were prescribed more frequently by specialists (88% vs 67%). The difference was statistically significant ($P<.05$). Specialists also used double doses of nasal corticosteroids more frequently (25% vs 11%).

Oral H_1-antihistamines were prescribed as daily medication by 77% of specialists and by 66% of GPs (not significantly different). Topical nasal H_1-antihistamines were rarely prescribed (4% in each group). Combined daily therapy with nasal corticosteroids and oral H_1-antihistamines was prescribed by 41% of GPs and 66% of specialists ($P<.01$).

The Table also shows that specialists prescribed nasal lavages with saline more frequently, and almost always in association with nasal corticosteroids. Nasal decongestants were just slightly more popular with specialists than with GPs, but over 75% recommended their use for less than 15 days; a smaller proportion of GPs made this recommendation.

Systemic corticosteroids (oral and/or injectable) were prescribed significantly less frequently by specialists than by GPs. They were chosen by 6% of specialists for case 1 (predominant nasal obstruction) and by none for case 2 (predominant histamine-induced symptoms). The GPs used systemic corticosteroids in both cases, although less frequently in the second case.

Leukotriene receptor antagonists were prescribed more often in case 1 by both specialists and GPs, but the differences between the 2 groups were not significant.

One limitation of our study is that we used a questionnaire about theoretical patients rather than an analysis of real prescriptions. However, this is the only way to directly compare treatment choices by different professionals for the same patient. This approach has already been advocated and used by others [3,4].

In our study, nasal corticosteroids were prescribed by 67% of GPs. Although this percentage is significantly lower than that observed for the specialists (88%), our GPs performed reasonably well if we compare the results with those of other studies [5], possibly because we only included GPs with

Table. Choice of Drugs by Allergy Specialists (n=70) and General Practitioners (GPs) (n=397) for Treating Moderate to Severe Persistent Allergic Rhinitis[a]

[b]Predominant obstructive symptoms.
[c]Predominant histamine-induced symptoms.

experience in treating allergic rhinitis. In a Belgian study, 66% of 95 GPs used nasal corticosteroids for the treatment of moderate to severe persistent allergic rhinitis while 54% used these corticosteroids in association with oral H_1-antihistamines [6]. It is worth mentioning that even among specialists, adherence to the use of nasal corticosteroids for moderate to severe rhinitis was not 100%, a finding that coincides with previous reports [2].

In our study, combined daily therapy with nasal corticosteroids and oral H_1-antihistamines was frequently prescribed to treat moderate to severe persistent allergic rhinitis by both GPs and specialists. The rate of prescription is similar to that reported by a Spanish study involving GPs and specialists, although that study did not distinguish between the prescription habits of GPs and specialists [7].

The use of such a combination therapy, even on a first visit, is in line with ARIA recommendations [8], which suggest that if symptoms are severe (as they were in our 2 cases), oral H_1-antihistamines should be added at the beginning of treatment. Step-down should only be undertaken after assessment of clinical improvement, at least after 2 to 4 weeks of treatment.

Our study provides confirmatory evidence that allergy specialists prescribe nasal corticosteroids significantly more frequently than GPs in the management of moderate to severe allergic rhinitis. However, it also indicates that approximately 67% of GPs with clinical experience in allergic rhinitis prescribe nasal corticosteroids as first-line therapy, at least for severe allergic rhinitis, and that 41% prescribe nasal corticosteroids in combination with oral H_1-antihistamines. Nonetheless, our study also shows that not all specialists (only 88% in our case) prescribe nasal corticosteroids to treat moderate to severe persistent allergic rhinitis, as would be expected.

Once again our results draw attention to the need for additional educational efforts to improve adherence to international guidelines, even among specialists, in order to provide patients with moderate to severe allergic rhinitis with the best treatment options available.

Necrobiotic Cutaneous Granulomas in Nijmegen Breakage Syndrome

S Pasic,[1] L Kandolf-Sekulovic,[2] S Djuricic,[1] L Zolotarevski,[2] R Simic,[1] M Abinun[3]
[1]Departments of Pediatric Immunology, Pathology and Surgery, Mother & Child Health Institute, Medical School, University of Belgrade, Serbia
[2]Departments of Dermatology and Pathology/Forensic Medicine, Medical Military Academy, Belgrade, Serbia
[3]Department of Pediatrics, Newcastle General Hospital, Newcastle upon-Tyne, United Kingdom

Key words: Nijmegen breakage syndrome. Immunodeficiency. Necrobiotic granuloma.

Palabras clave: Síndrome de Nijmegen. Inmunodeficiencia. Granuloma necrobiótico.

Nijmegen breakage syndrome (NBS) is a rare syndrome of chromosomal instability characterized by microcephaly, immunodeficiency, and predisposition to cancer at a young age [1]. Café-au-lait spots, vitiligo, and sun sensitivity of the eyelids are common skin findings [2]. Multiple pigmented nevi, cutaneous telangiectasia, and cavernous or flat hemangiomas are occasionally observed.

Skin and/or visceral granulomas are occasionally encountered in primary immunodeficiencies such as common variable immunodeficiency (CVID) and ataxia-telangiectasia [3,4]. In chronic granulomatous disease, an inherited deficiency of phagocytes, granulomas of visceral organs are common but skin granulomas are rarely observed. Recently, both necrotizing and sarcoid-like cutaneous granulomas were reported in 2 pediatric patients with NBS [5,6].

We report on a young adult patient with NBS who developed necrobiotic cutaneous granulomas.

A female patient with NBS came to our attention at 8 years of age when she was investigated for recurrent infections. Microcephaly (head circumference, 44 cm; <p3) and a bird-like facial appearance raised suspicion of immunodeficiency. The diagnosis of NBS was confirmed by mutation analysis of the *NBS1* gene, which revealed the typical, homozygous 5 base-pair deletion (del.657A). She was started on monthly intravenous immunoglobulin (IVIG) replacement therapy. At 10 years of age she developed T-cell lymphoblastic leukemia/lymphoma, which was successfully treated with standard chemotherapy.

At 21 years of age she developed subcutaneous livid and hyperpigmented nodules on her calves associated with inguinal lymph node enlargement. She had no fever, weight loss, or other signs of systemic infection. Laboratory investigations revealed an erythrocyte sedimentation rate of 30 mm/h, a hemoglobin level of 116 g/L, a white blood cell count of 2.0×10^9/L, and a platelet count of 118×10^9/L. Immunophenotyping of bone marrow aspirate excluded lymphoproliferative disease. Phenotypic analysis of peripheral blood lymphocytes revealed

A

B

Figure. A, Facial granulomas. B, Generalized lymphoedema associated with multiple granulomatous nodules and deep skin ulcers.

decreased absolute $CD3^+$, $CD4^+$, and $CD8^+$ lymphocyte counts. A chest radiograph and thoracic and abdominal magnetic resonance imaging scans were all normal.

Histopathologic examination of skin and inguinal lymph node biopsy specimens revealed well-defined necrobiotic granulomas with mononuclear infiltrate, abundant histiocytes, and multinucleated giant cells of Langhans type. The lymphocytic infiltrate was comprised of $CD3^+$ lymphocytes (CD4:CD8 ratio, 1.5:1), few foci of $CD20^+$ lymphocytes, and scarce $CD1a^+$ cells, while no immunoreactivity was evident for TdT or CD99. Special stainings and cultures for fungi and mycobacteria were all negative. Polymerase chain reaction–based assays for detection of nontuberculous mycobacteria were also negative.

Because infection with nontuberculous mycobacteria was suspected initially, several antituberculosis drugs were given, but there was no response. Two months later, new granulomas were noticed on the face (Figure 1A; informed consent obtained). The patient refused any further treatment and was lost to follow-up.

Six months later, she was admitted with worsening of lymphoedema with multiple, hyperpigmented nodules and widespread, deep skin ulcers (Figure 1B). Microbiological cultures obtained from skin ulcers grew *Staphylococcus aureus* and *Pseudomonas* species. Histological examination of a skin biopsy specimen reconfirmed necrobiotic granulomatous dermatitis. Treatment consisted of intravenous co-trimoxazole for 2 weeks followed by 5 pulses of methylprednisolone (1.5 mg/kg/d), doxycycline 100 mg twice daily, and IVIG replacement. Topical treatment included necrectomy, antiseptic compresses, and silver sulfadiazine cream. Depot steroid injections and doxycycline were continued and resulted in almost complete healing of the skin ulcers and regression of the granulomas.

NBS should be suspected in pediatric patients with microcephaly presenting with a history of recurrent infections or lymphoma. Additional features of NBS include various cutaneous lesions but cutaneous granulomas are only rarely reported. Vogel et al [5] reported necrotizing skin granulomas, complicated by *Pseudomonas* species superinfection and osteomyelitis, in a 7-year-old patient with NBS [5], while Yoo et al [6] reported sarcoid-like granulomas in another pediatric patient with NBS.

Skin and/or visceral sarcoid-like granulomas, or less commonly, caseating or necrobiotic granulomas, are most frequently observed in CVID, with a reported incidence of between 8% and 20% [3]. Recently, Schuez et al [7] reported skin and visceral noncaseating granulomas in combined immunodeficiency due to mutations in recombinase-activating genes.

The infectious etiology of granulomas in PID is elusive. Granulomas may be noninfectious, immune-mediated lesions associated with defects of cellular immunity [8]. In the granulomatous form of CVID, cellular immunity defects, mainly $CD4^+$ lymphocytopenia, lead to a state termed *immune dysregulation*; this is characterized by persistent activation of tumor necrosis-factor (TNF) α, which is important for both granuloma formation and persistence [8]. In NBS, approximately 80% of patients develop profound $CD4^+$ lymphocytopenia, so similar mechanisms may contribute to granuloma formation.

As occurs in CVID, treatment with corticosteroids led to resolution of the granulomas in our patient [3]. In CVID, some nonresponders to corticosteroids, anti-TNF, or anti-TNF receptor recombinant fusion monoclonal antibodies such as infliximab or etanercept have been used with varying success [9,10]. However, anti-TNF agents should be avoided in NBS because they can increase the existing risk of lymphoma.

Corticosteroid treatment of long-standing, necrotizing skin granulomas was found to be unsuccessful in a single pediatric patient with NBS [5]. Of interest, this patient developed non-Hodgkin lymphoma and the use of chemotherapy including rituximab resulted in significant healing of granulomas.

We have reported a case of necrobiotic cutaneous granulomas in an adult patient with NBS who responded favorably to intensive antibiotic and immunosuppressive treatment with topical and systemic corticosteroids.

Allergy to Red Currant: Immunoglobulin E–Mediated Hypersensitivity to Lipid Transport Proteins (Pru p 3)

M Tomás,[1] A Álvarez-Perea,[1] A Ledesma,[2] ML Baeza,[1] M de Barrio[1]
[1]*Allergy Service, Hospital General Universitario Gregorio Marañón, Madrid, Spain*
[2]*Departamento de I+D, ALK Abelló SA, Madrid, Spain*

Key words: Red currant. Rosaceae fruit allergy. LTP. Pru p 3.

Palabras clave: Grosella. Alergia a frutas rosáceas. LTP. Pru p 3.

Individuals who are allergic to vegetables commonly react to other phylogenetically unrelated foods as a consequence of sensitization to panallergens. Profilin and lipid transport protein (LTP) are the most frequent panllergens.

In Spain, the most frequent cause of food allergy is the Rosaceae family. Peach LTP (Pru p 3) is a major allergen in southern Europe. It causes severe reactions in allergic patients and has been associated with allergy to other Rosaceae, mainly apricot, cherry, and walnut.

Red currant is the fruit of *Ribes rubrum*, a deciduous bush from western Europe that belongs to the Grosuraliceae family. It is widely used in western countries because of its high content in vitamin C and carotenes and its powerful antioxidant properties.

Allergy to red currant is rare. We present a case of red currant–induced anaphylaxis that was diagnosed based on a suggestive history, positive skin test results, and determination of specific immunoglobulin (Ig) E. The presence of panallergens accounting for concomitant presence of food allergy and pollinosis was also studied.

A 19-year-old woman with a history of urticaria-angioedema in childhood due to sunflower seeds and peanut consulted after developing malaise, palpebral and genital angioedema, erythema on her face and neck, systemic hives, pruritus, and dysphonia immediately after eating duck meat with red currant sauce and lettuce with walnuts and goat cheese. After this episode, she tolerated almonds, sunflower seeds, pistachio, duck and other bird meats, onions peach, lettuce, and walnut.

Skin prick tests (SPT) were positive to grass pollen, *Artemisia vulgaris* and *Platanus acerifolia* pollen, peanut, walnut, chestnut, sunflower seed, apple, peach, and onion; prick-by-prick testing was positive to red currant and plum. SPTs with lettuce, pistachio, soy, strawberry, carrot, mustard, *Anisakis simplex*, and other pollens were negative.

Total IgE was 138 kU_A/L. Specific IgE (CAP, Phadia, Uppsala, Sweden) levels (kU_A/L) were as follows: *Artemisia vulgaris*, 1.54; *Chenopodium album*, 0.38; *Platanus acerifolia*, 0.59; strawberry, 0.67; apple, 3.63; peach, 7.71; plum, 0.70; onion, 0.45; peanut, 1.13; chestnut, 1.24; walnut, 2.82; and pistachio, 0.38. Specific IgE to Pru p 3 by CAP Pharmacia was 17.03 kU_A/L.

IgE to red currant was positive by enzyme-linked immunosorbent assay. An allergenic extract was prepared, and IgE immunoblot of the patient's serum revealed a single 14-kD band. Polyclonal rabbit serum was used to reveal the

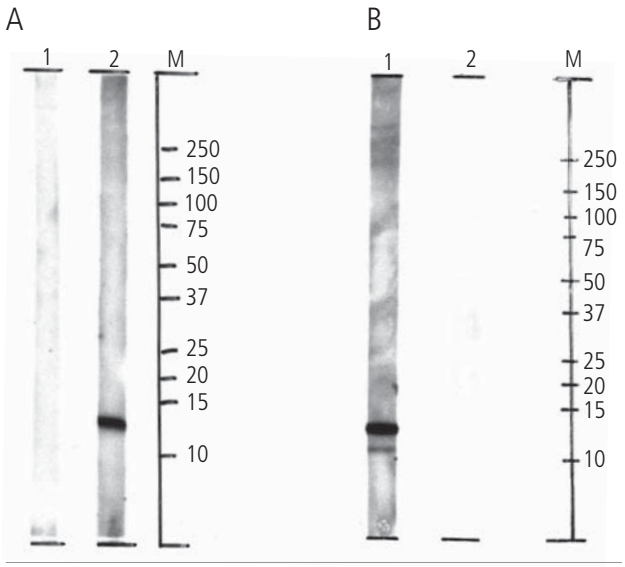

Figure. A, Immunoglobulin (Ig) E immunodetection with the currant extract: lane 1, negative control; lane 2, patient's serum. B, Immunoblotting with polyclonal antiserum: lane 1, red currant polyclonal antiserum; lane 2, negative control. M indicates molecular weight (kDa).

presence of Pru p 3 in the red currant extract (14 kD) (Figure). The 14-kD band specifically recognized by the patient's serum seemed likely to be an LTP.

Fruit and nuts, followed by legumes and vegetables, are the most common cause of food allergy in adults in Spain [1]. Many patients are sensitized to multiple foods, and in some cases sensitization is associated with pollen allergy. The sensitization pattern varies depending on the aerobiology of the area where the patient lives.

Birch pollen has been related to food allergy in northern Europe and in some regions of North America and Australia. However, birch trees are uncommon in Spain, and allergy to Rosaceae is more usually linked to grass pollen–fruit allergy syndrome.

These associations are based on the existence of IgE-mediated cross-reactivity. The most well known panallergens are Bet v 1 counterparts, profilins, and LTP [2], which have been identified as major allergens of some Rosaceae fruits. These proteins are highly stable, thus enabling them to cause severe systemic reactions (anaphylaxis, generalized urticaria).

Increasing levels of IgE to peach LTP are associated with skin reactivity to nuts, peanut, maize, rice, onion, orange, celery, and tomato [3]. Some studies suggest that high levels of IgE target common allergenic determinants of LTP, causing cross-reactivity to botanically unrelated vegetable foods in LTP-allergic patients [3].

However, although sensitization to LTP is not uncommon in pollen-allergic patients [4] and cross-reactivity in skin or in vitro tests is frequent in this population, the clinical significance of this cross-reactivity is often unknown, and a complete clinical history or challenge test is often necessary to determine whether a certain food must be avoided [5]. Skin test results can remain positive, even when the culprit food is tolerated, as was the case with our patient.

Allergy to red currant is rare, and only 3 cases of systemic reaction have been reported [6-8]. Our group reported a case of anaphylaxis after ingestion of red currant in a patient with pollinosis, globus sensation, and dysphagia with peach, apricot, and nectarine. The patient had specific IgE to currant and tolerated other Rosaceae fruits. Cross-reactivity between pollens and Rosaceae fruit allergens was demonstrated using CAP and immunoblot [8].

We present the case of a patient with subclinical pollen sensitization who suffered an episode of anaphylaxis after ingestion of red currant and was diagnosed with allergy by skin and in vitro tests. These studies demonstrated the presence of panallergens (LTP) in our red currant extract. Specific IgE to LTP is very likely to be the causative agent of concomitant pollen and food allergy sensitization.

Further studies are necessary to describe other allergenic components of red currant, since the increasing importance of this fruit in western society may cause a higher rate of allergic reactions in the near future.

Occupational Allergic Contact Urticaria to Crustacean in a Cook

G Pala,[1] P Pignatti,[1] L Perfetti,[1] E Gentile,[2] G Moscato[1]
[1]*Allergy and Immunology Unit, Fondazione 'Salvatore Maugeri', Institute of Care and Research, Scientific Institute of Pavia, Pavia, Italy*
[2]*Specialization School in Occupational Medicine, University of Pavia, Pavia, Italy*

Key words: Occupational allergy. Contact urticaria. Crustacean. Seafood allergy. Cook.

Palabras clave: Alergia ocupacional. Urticaria de contacto. Crustáceos. Alergia marisco. Cocinero.

Contact urticaria (CU) to crustacean is common in the general population, but its prevalence in occupational settings is largely unstudied. Although reactions to seafood have been documented, mainly among consumers, immune-mediated reactions have also been reported at work, especially in the fishing and seafood processing industry [1,2]. The few cases reported among cooks were associated with oral allergy syndrome [3,4]. We report on a 33-year-old man who experienced wheals and flares after contact with the juice of frozen crab, water used for cooking lobster, and fresh shrimp. No symptoms were reported after ingestion of crustacean or after contact with or ingestion of other foods. Symptoms appeared 17 years after working as a cook. We performed skin prick tests (SPT), specific immunoglobulin (Ig) E determination, and the basophil activation test with common allergens and crustacean (Table). We also performed SPTs and patch tests with freshly prepared extracts of crab and lobster juice. Patch tests were performed on the back, both on unimpaired skin and after scratching with a cotton swab drenched in alcohol (Table). The blood differential test revealed 6.2% eosinophils, and total serum IgE was 19.7 kU_A/L. The results of SPTs and patch tests with freshly prepared extracts performed on 3 healthy controls were negative. In addition, immunoblotting with commercial crustacean extracts revealed no IgE-binding protein in serum. A diagnosis of occupational CU induced by crustacean was made, and the patient was advised to avoid any contact with this food.

To our knowledge, this is the first report of occupational CU due to crustacean (crab, lobster, and shrimp) in a cook with no symptoms after ingestion. Denaturation of proteins during digestion may explain the absence of symptoms after ingestion. The absence of IgE-binding proteins in immunoblotting could account for the low total IgE levels. Positive skin test results with both raw and cooked crustacean (Table) suggest the involvement of a heat-resistant protein. Finally, the absence of sensitization to mite and detection of the negative tropomyosin (rPen a1) suggest primary sensitization to a cross-reactive crustacean allergen other than tropomyosin.

Hyperimmunoglobulin E Syndrome Presenting With Renal Abscess

H Yuksekkaya,[1] O Ozbek,[2] F Goncu,[3] M Keser,[4] H Artac,[5] P Harun,[5] S Keles[5]

Key words: Renal abscess. Hyper-IgE syndrome.

Palabras clave: Absceso renal. Síndrome de hiper-IgE.

Hyperimmunoglobulin E syndrome (HIES), also known as Job syndrome, is a very rare primary immunodeficiency characterized by the clinical triad of high serum immunoglobulin (Ig) E levels (>2000 IU/mL), recurring staphylococcal skin abscesses, and pneumonia with formation of pneumatocele. Host defense deficiencies in HIES include reduced neutrophil chemotaxis, impaired phagocytosis, and variably impaired T-cell function. Infections are mainly caused by *Staphylococcus aureus* and *Streptococcus pneumoniae* [1,2]. We report a case of multiple renal abscesses in a patient with HIES.

A 4-year-old girl was referred to our clinic with abdominal distension, diarrhea, fever, and failure to thrive. Her clinical history revealed 2 episodes of persistent diarrhea lasting 3-4 weeks 2 years previously. An impetigo-like skin lesion appeared intermittently on her chin. Her parents were not consanguineous, and she had 3 healthy siblings. Physical examination revealed her height and weight to be in the third percentile. Hepatosplenomegaly was not observed, and a review of her body systems was unremarkable. Interestingly, respiratory function was not tested before admission. Nevertheless, chest x-rays and computed tomography of the thorax revealed bronchiectasis in the right lung. Blood pressure was within normal ranges, but she had tachycardia and fever. Abnormal blood test results included the following: hemoglobin, 5 g/dL; white blood cell count, 16 200/mm^3; erythrocyte sedimentation rate, 140 mm/h; and C-reactive protein, 120 mg/L (reference range, 0-5 mg/L). Other test results were normal. Urinalysis revealed large numbers of leukocytes and bacteria. The results of liver and kidney function testing were normal. Peripheral blood smear revealed an eosinophil percentage of 30%. The remaining test results were as follows: iron <10 μg/dL; iron-binding capacity, 136 μg/dL; ferritin, 268 μg/L (28-365); vitamin B12, 192 pg/mL (190-450); and folic acid, 2.4 ng/mL (3-12). Stool samples and blood cultures were negative. Ceftriaxone was started empirically because of fever. The urine culture antibiogram revealed methicillin-resistant *S aureus* (100 000 colonies/mL), which was sensitive to clindamycin. Ceftriaxone was switched to clindamycin. We initially considered the possibility of celiac disease because of the abdominal distension, severe anemia, and low folic acid level, but the results of celiac antibody testing were negative. Abdominal ultrasound and subsequent computed tomography revealed bilateral nephromegaly, bilateral multiple parenchymal abscesses, and an abscess measuring 4 × 5 cm in diameter affecting the calyces of the left kidney (Figure). Ultrasound-guided percutaneous nephrostomy was performed and a drainage tube inserted for 2 weeks. *S aureus* was isolated in the drainage fluid and in urine. The immunological workup revealed elevated IgE titers (up to 13 000 IU/mL) and an eosinophil count of up to 3900 cells/μL. Titers for IgG, IgA, IgM, and IgG were normal. Analysis of the lymphocyte subpopulation revealed normal B- and T-lymphocyte counts. Delayed-type hypersensitivity reaction to the tuberculin skin test was negative. Lymphocyte proliferation was normal on stimulation with mitogen. Neutrophil functional responses were assessed using flow cytometry. Neutrophil chemotaxis was significantly impaired. The patient had a homozygous deletion starting in exon 28 and extending to the terminal exon; there was no mutation in *STAT3* gene. The patient was diagnosed with HIES (HIES score, 31). The abscesses began to decrease in size after

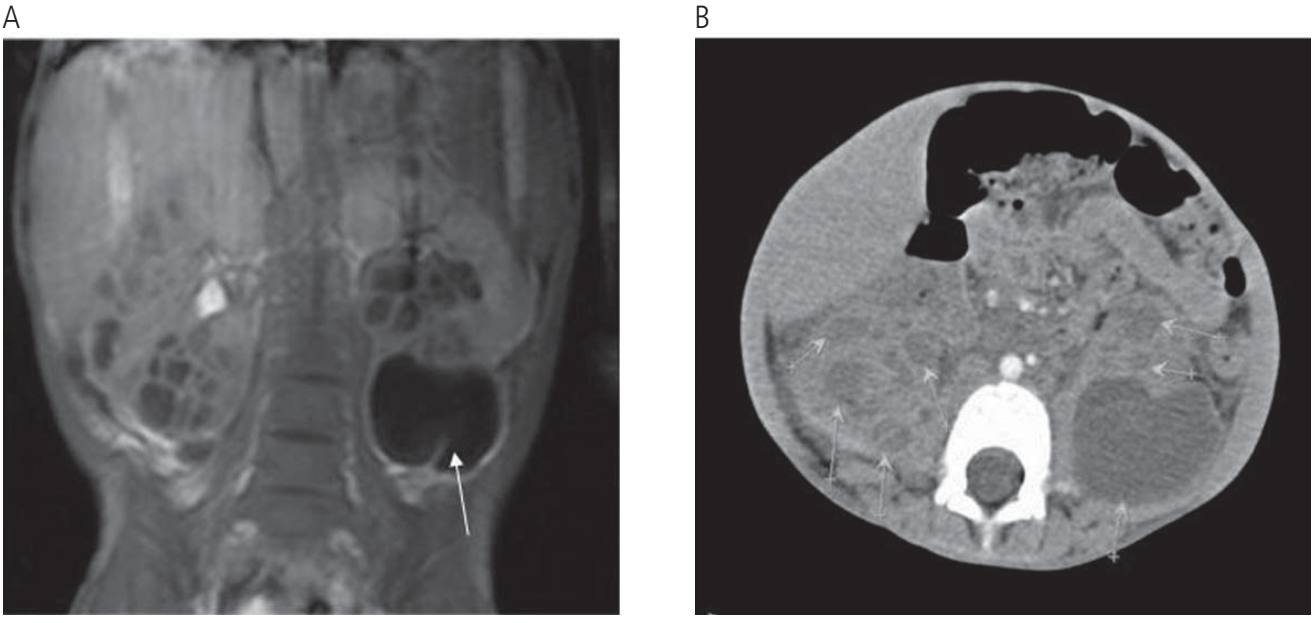

Figure. Bilateral multiple renal abscesses. A, T1-weighed magnetic resonance image of the abdomen. B, Computed tomography image of the abdomen.

10 days with clindamycin and had disappeared by the third week on ultrasound. Clindamycin was continued for 2 months. The patient was discharged, low doses of prophylactic antibiotic (cotrimoxazole, 4 mg/kg/d) were started, and intravenous immunoglobulin was continued every 3 weeks. The follow-up examination at 15 months was unremarkable.

Renal abscess is a rare disease in childhood, although it involves potentially fatal complications (urinary tract infections or bacteremia). It can result from hematogenous spread or as a complication of infection from the lower urinary tract. *S aureus* and *Escherichia coli* are the most commonly isolated pathogens [3,4]. In HIES, however, infections are caused mainly by *S aureus* or *S pneumoniae* [1]. In our case, there was no vesicoureteral reflux or anatomical problem. *S aureus* was isolated in both urine and abscess drainage fluid. In addition to classic findings, HIES is characterized by conditions such as tuberculous brain abscess [5], endocarditis, and epidural abscess [6], although disseminated renal abscesses have not been described. To our knowledge, this is the first case of disseminated multiple renal abscesses in a patient with HIES to be reported in the English-language literature.

No cure is available for HIES. When abscesses, skin lesions, and pneumonia have developed, long-term high-dose intravenous antibiotics are required to eliminate infectious agents, and surgical drainage may occasionally be necessary [7]. Therapy with intravenous immunoglobulin can affect IgE levels owing to increased immunoglobulin catabolism or IgE neutralization via an anti-idiotype network [8]. Renal abscesses can be managed by medical treatment alone; interventional treatment should be reserved for large collections of abscesses and patients with clinical impairment. Perinephric and mixed abscesses can be successfully managed by interventional treatment. Abscesses >5 cm or those that fail to respond to antibiotic treatment should be considered for drainage guided by ultrasound or computed tomography [4,9]. Our patient had both an abscess of approximately 5 cm in diameter and immunodeficiency. We performed percutaneous drainage and administered intravenous immunoglobulin. We did not consider a surgical intervention because of the disseminated parenchymal renal abscesses.

Vancomycin and cefepime are excellent choices to treat suspected renal abscess in a previously healthy child [10]; however, we preferred to use clindamycin, which completely penetrates the abscess. The role of long-term prophylactic antibiotic therapy has not been closely investigated in patients with HIES, but the consensus of opinion favors prophylactic therapy with an antistaphylococcal antibiotics such as cotrimoxazole or cephalosporin [2]. We prescribed cotrimoxazole as prophylaxis and therapy with intravenous immunoglobulin; our patient did not have to be hospitalized during her 15 months of follow-up.

In conclusion, disseminated renal abscess rarely progresses to HIES. The most important causal agent of renal abscess is *S aureus*, both in HIES and in other tissue abscesses. Clindamycin with drainage is a sound choice for the treatment of renal abscesses.

Acknowledgments

A Case of Allergic Bronchopulmonary Aspergillosis Treated With Omalizumab

I Sastre, J Blanco, H Mata, F García
Unidad de Alergología, Complejo Asistencial Universitario de Burgos, Burgos, Spain

Key words: Aspergilosis. *Aspergillus*. Omalizumab.

Palabras clave: Aspergillosis. *Aspergillus*. Omalizumab.

Allergic bronchopulmonary aspergillosis (ABPA) is an inflammatory lung disease of immune origin that usually occurs as a complication of allergic asthma or cystic fibrosis. It is characterized by reversible airway obstruction, transient pulmonary infiltrates, eosinophilia, and fever and is caused by an immunoglobulin (Ig) E–mediated hypersensitivity response to *Aspergillus fumigatus*, which colonizes the bronchial tree [1].

We present the case of a 33-year-old woman with a 6-month history of dyspnea and wheezing. Her blood count was normal, and there were no relevant findings in the chest x-ray or paranasal sinuses. Total IgE was >1000 IU/mL. Spirometry revealed an obstructive pattern, and the result of the bronchodilation test was positive. Skin tests were positive for *A fumigatus* (12 mm) and *Penicillium notatum* (10 mm). Precipitins against *A fumigatus* were also measured, and the results were negative.

The patient was diagnosed with allergic bronchial asthma. In the following years she reported worsening of clinical symptoms associated with cough, brown expectoration, and dyspnea on exertion. Determinations were repeated and disclosed eosinophilia (1100/mm^3). Chest x-ray revealed an infiltrate in the middle lobe of the right lung.

Skin tests were positive to *A fumigatus* (10 mm). Total IgE was 3090 IU/mL, specific IgE to *A fumigatus* was 86 kU_A/L, and determination of IgG and precipitins to *A fumigatus* was positive. The patient was diagnosed with ABPA and started treatment with prednisone 0.5 mg/kg/d.

In the following years, her progress was unsatisfactory, with several acute exacerbations. She continued to receive prednisone at a maintenance dose of 15 mg every other day. Spirometry revealed the following values: forced vital capacity (FVC), 2250 mL (75%); forced expiratory volume in the first second of expiration (FEV_1), 1370 mL (60%); and FEV_1/FVC, 60%. Determination of IgE specific to recombinant *A fumigatus* antigens provided the following values: rAsp f 1, 9.45 kU_A/L; rAsp f 2, 2.12 kU_A/L; rAsp f 3, 6.94 kU_A/L; rAsp f 4, 2.39 kU_A/L; and rAsp f 6, <0.35 kU_A/L.

Thoracic computed tomography (CT) revealed bronchiectasis in the middle and right upper lobes.

In order to reduce systemic corticosteroids and improve disease outcome, treatment was started with itraconazole [2] at 200 mg/12 h, although it was discontinued because of lack of improvement in clinical, laboratory, and spirometry parameters. The patient experienced an acute exacerbation and prednisone-induced side effects (cushingoid facies), and liver enzyme values increased.

In July 2009, at 53 years of age, she started treatment with

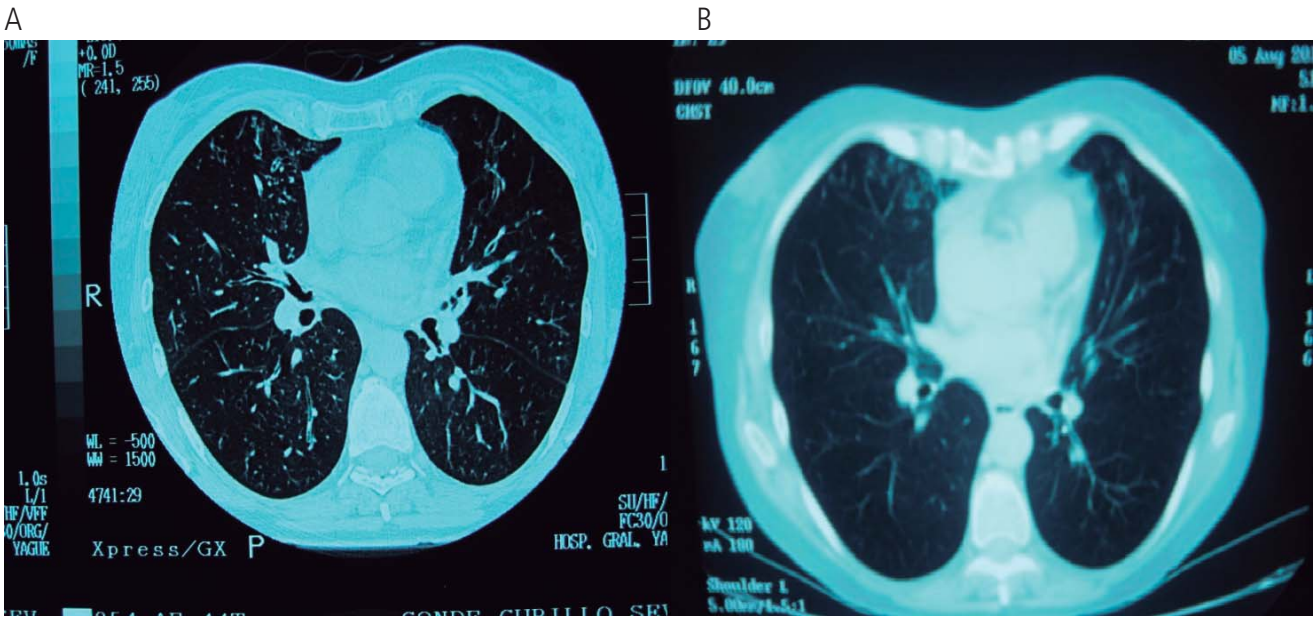

Figure. Computed tomography scan showing reduced bronchiectasis after 12 months of treatment with omalizumab. Left, Before therapy with omalizumab. Right, After therapy with omalizumab..

omalizumab at 375 mg/2 wk. After 3 months of treatment, her clinical condition improved, with reduced cough and expectoration. The dose of prednisone was reduced to 5 mg/48 h of prednisone. The last spirometry test, performed in July 2010, disclosed the following values: FVC, 2890 mL (97.5%); FEV_1, 1620 mL (72.6%); and FEV_1/FVC, 70.7%.

No new acute exacerbations were detected in this 12-month period.

A second thoracic CT scan revealed persistent bilateral bronchiectasis at multiple levels with less bronchial wall thickening (indicative of remission of inflammation), as well as a lower degree of bronchiectasis and a reduced number of micronodular peribronchial opacities (indicative of reduced impaction and inflammation of the distal airways) (Figure).

ABPA is an inflammatory lung disease of immune origin that manifests as an IgE-mediated type I hypersensitivity response to *A fumigatus* antigens in the bronchial tree. It is associated with the toxic action of enzymes released by the mold in the bronchial tree.

The disease consists of 5 stages, ranging from the acute stage (pulmonary infiltrate, eosinophilia, and increased total IgE) to pulmonary fibrosis. Our patient's disease was in stage IV (corticosteroid-dependent stage), in which treatment with systemic corticosteroids cannot be discontinued, as new acute exacerbations may occur.

Omalizumab is a humanized recombinant monoclonal antibody that selectively binds to IgE to inhibit the immune response to an allergen. It targets the high affinity Fc receptor and prevents free serum IgE from binding to mast cells and other effector cells, in turn preventing IgE-mediated inflammation. It is indicated mainly for the treatment of persistent allergic bronchial asthma that is not well controlled with other treatments. However, it is increasingly successful in several IgE-mediated conditions. Five case reports of ABPA have been published to date, and all were recorded in patients with cystic fibrosis whose clinical condition improved. In all 5 cases, the dose of systemic corticosteroids was reduced without starting treatment with omalizumab [3-7].

We report a case of corticosteroid-dependent ABPA (stage IV) with unsatisfactory clinical progress and multiple acute exacerbations for which no response was obtained with antifungals. The patient's condition improved considerably after starting treatment with omalizumab. No new acute exacerbations were recorded, and the dose of systemic corticosteroids was reduced by 70%. Furthermore, a significant improvement in respiratory function and radiological findings was observed in the last CT scan. This is the first case in which such an improvement has been observed.

As ABPA is an inflammatory disease of which the main cause is a type I hypersensitivity mechanism mediated by IgE against *A fumigatus* antigens, the use of omalizumab can improve disease control during the corticosteroid-dependent stage. Use of this agent could be extended in the event of recurrences in order to prevent progression to subsequent stages.

Acknowledgments

Threshold Doses in Specific Oral Tolerance Induction in Children With Egg Allergy

A Letrán, M Espinazo, MC López, FJ Caro, L Gómez, P Lobatón, J Dafonte, F Moreno
Clínica Dr. Lobatón, Cádiz, Spain

Key words: Egg allergy. Egg immunotherapy. Food allergy. Specific oral tolerance induction.

Palabras clave: Alergia a huevo. Inmunoterapia frente a huevo. Alergia alimentaria. Inducción de tolerancia oral específica.

The current standard of care for egg allergy includes strict allergen avoidance and ready access to adequate pharmacotherapy in the event of accidental ingestion. Although most patients outgrow their allergy over time, some continue to have reactions over many years. Therefore, specific oral tolerance induction (SOTI) protocols have been developed. Tolerance is achieved by administering small doses, which are increased slowly to an amount equivalent to the usual daily oral intake. Subsequently, egg is given daily at a maintenance dose [1,2].

We present our experience with an open egg SOTI protocol in children with persistent egg allergy. We recorded age, sex, last documented adverse reaction with egg, skin prick test results (mm), total-specific immunoglobulin (Ig) E titers (IU/mL), other allergic comorbid conditions, and threshold doses for each visit. The number and type of secondary effects of SOTI and their treatment were evaluated. The exclusion criteria were a history of anaphylaxis to egg within 6 months of beginning the protocol, uncontrolled asthma, and severe atopic dermatitis. Written informed consent was obtained in all cases.

With a target tolerance of 1 complete egg, we mixed a whole large size raw egg with cow or soymilk yogurt (0.09 g/mL of ovalbumin [OVA] and 0.02 g/mL of ovomucoid [OVM]) [3]. SOTI was initiated at our clinic with a placebo control from a low initial dose (0.01 mL of mixture), which was doubled every 20 minutes. Peak expiratory flow and blood pressure were recorded (build-up phase). Patients subsequently repeated the last tolerated dose every day at home (maintenance phase), thus providing the first step for the next visit. Maintenance consisted of the daily administration of the corresponding tolerated part of a similar-size 1-egg omelet. Visits were programmed on a monthly basis.

The initial sample comprised 17 patients (11 boys, 6 girls); 6 patients completed the entire protocol and 3 patients dropped out. Mean age at enrollment was 8 years (range, 4-14 years). The most common symptoms related to prior exposure to egg were urticarial rash (7 patients) and anaphylaxis (6 patients). Thirteen patients (75%) had already had a positive response in an open challenge with raw egg white (average of 6 months before) and the rest (25%) had had a recent direct adverse reaction to egg. Five patients (29%) had atopic dermatitis.

In general, the build-up phase was well tolerated with no need for intramuscular adrenaline, intravenous fluids, or oxygen treatment. At the first visit, the median tolerated dose was 1.6 mL (corresponding to 0.284 accumulated grams of OVA and 0.063 accumulated grams of OVM: 1/65 of the whole egg). All the patients except 2 (patients 8 and 9) received more than 3 doses at this visit. One patient (patient 8) developed intense abdominal pain and vomited with the first dose; therefore, the protocol was stopped. Patient 13 experienced respiratory symptoms (0.2-mL dose) that resolved with $ß_2$-agonists and did not prevent the protocol from continuing. The median tolerated dose at the second visit was 4.8 mL (0.869 accumulated grams of OVA and 0.195 accumulated grams of OVM: 1/17 of the whole egg). In 2 cases, the dose achieved at the first visit could not be increased: in one patient (patient 8) from 0.01 mL, because of acute rhinoconjunctivitis, and in the other (patient 6) from 6.4 mL, because of abdominal pain and emesis. The first patient received a short cycle of systemic corticosteroids. The median tolerated dose for the third and fourth visits were 9.6 mL (1/9) and 12.8 mL (1/8), respectively. No more than 7 visits were recorded.

Few severe adverse reactions were recorded during the maintenance phase. Eight children (47%) experienced intermittent self-limiting mild oral pruritus with no systemic symptoms. One patient (number 15) developed generalized urticaria at home with the previously tolerated dose of 12.8 mL when ingestion coincided with ibuprofen treatment (second dropout). Patient 3 had facial angioedema and dyspnea at the previous tolerated dose of 25.6 mL (1/4) and had to attend the emergency department. The parents did not report any concomitant fact that could explain the reaction.

[a]Final dose of the protocol.

After starting with a low dose at the first visit (1/65 of the egg), we observed that most patients were able to tolerate greater doses at each subsequent visit (3-fold from the first to the second visit and 2.5-fold with the following steps until the fourth visit). Consistent with published data, it is recommended that food challenge should start with an individualized dose based on the clinical history that is generally lower than the quantity that caused the symptoms [4,5]. The position paper of the European Academy of Allergology and Clinical Immunology proposes starting food challenge with 1 mg of egg [6]. However, in our opinion, this approach is subject to practical drawbacks owing to an incomplete standardization procedure and the difficulty involved in trying to divide a cooked or raw egg into equal parts and start the protocol with a high initial dose (1/16, 1/8). If the challenge result is positive, we should wait as long as is necessary until natural tolerance is achieved. Consequently, we are faced with a series of questions. First, even though food challenge is the current gold standard in food allergy, can we use protocols such as ours both to monitor and to induce tolerance? Is it always necessary to expose the patient to a risky amount of egg before SOTI? Is it so important to perform a food challenge before SOTI if both approaches involve controlled exposure? We used egg SOTI as the only challenge method and postulate that it could replace the classic food challenge.

Diagnosis of Autosomal-dominant Hyperimmunoglobulin E Syndrome

P Garcés,[1,3] F Garcia-Martin,[2] D Detkova,[1] T Espanol[1]
[1]*Immunology Unit, University Hospital Vall d'Hebron, Barcelona.*
[2]*Infectious and Immunodeficiencies Unit, Hospital Carlos Haya, Malaga, Spain*
[3]*Hospital Hernan Henriquez Aravena, Temuco, Chile*

Key words: Hyper-IgE syndrome. *STAT3* mutations. Autosomal-dominant inheritance

Palabras clave: Síndrome de Hiper-IgE. Mutaciones en STAT3. Herencia autosómica-dominante.

Hyperimmunoglobulin E syndrome (HIES) is a primary immunodeficiency with immunological and nonimmunological manifestations [1,2]. The main immunological manifestations comprise high serum immunoglobulin (Ig) E levels, eosinophilia, eczema, and skin and lung infections; the main nonimmunological features are facies, scoliosis, retained primary teeth, joint hyperextensibility, bone fractures following minimal trauma, and craniosynostosis. Such a broad spectrum can make diagnosis difficult, and typical features may become apparent over time, when bone and dental abnormalities appear. In pediatric patients, a differential diagnosis with severe atopy [3,4], eczema, and relatively high IgE titers is mandatory in children with no family history of this disease. Hence, any diagnostic algorithm is likely to underdiagnose younger patients. Furthermore, recently published score values [5] are not always helpful in pediatric patients. Both autosomal-dominant inheritance traits (AD-HIES) and autosomal-recessive inheritance traits (AR-HIES) have been described. Heterozygous mutations in the signal transducer and activator of transcription 3 gene (*STAT3*) have been identified in patients with AD-HIES [6,7], whereas homozygous mutations in the dedicator of cytokinesis 8 gene (*DOCK8*) have been associated with the recessive form of the disease [8]. We report 3 pediatric cases of AD-HIES diagnosed at our center over the last 30 years and highlight the differences in presentation and prognosis.

We reviewed the clinical histories of 3 patients diagnosed with HIES from 1980 to the present. Ig levels (IgE and IgG) and lymphocyte subsets were measured using routine laboratory techniques. When possible, genetic testing for mutations in *STAT3* was performed at the Royal Free Hospital, London, UK, after written informed consent was obtained from the parents (Table).

Patient 1

A 2-month-old boy presented with eczema that appeared during the first month of life and led to severe infections (generalized impetigo and skin abscesses). He also suffered from recurrent episodes of thrush and respiratory infections. At the age of 13 months, he underwent lobectomy for removal of a pneumatocele in the left lung. The patient developed

bronchiectasis; clinical manifestations included acropachy and episodes of hemoptysis. Despite antibiotics and therapy with intramuscular immunoglobulin, the patient died at the age of 14 years (1987), before the results of the genetic study became available. Given the severity of the disease, high National Institutes of Health score, and similarities with other cases, the patient was considered to have AD-HIES.

Patient 2

A 17-month-old girl (nonconsanguineous parents) developed *Pneumocystis jiroveci*–induced pneumonia at the age of 3 months. She had also had oral thrush and atopic eczema since birth. Severe combined immunodeficiency and phagocytic disorder were ruled out at that point.

At 2 years of age, she presented with lung abscesses complicated by pneumothorax, subcutaneous emphysema, and pneumatocele. Segmentectomy and several courses of antibiotics were required and treatment with intravenous immunoglobulin was initiated. Laboratory analyses revealed hypereosinophilia and hypergammaglobulinemia.

Since then, the patient has presented several bacterial infections, aspergilloma, and recurrent life-threatening episodes of hemoptysis.

Today, she has typical HIES facies (high palate, wide nasal bridge) joint hyperextensibility, and discrete scoliosis and is receiving intravenous immunoglobulin and prophylaxis with antibiotics and antifungals. The mutation in *STAT3* was confirmed in 2007.

Table. Clinical, Immunological, and Mutation Data

Patient No./Sex	1/Male	2/Female	3/Male
Age at diagnosis/current age, y	7/died at 14 y	4/17	3/died at 4 y
NIH score[a]	74	67	41
IgE, IU/mL	>4000	13 800	880

Microorganisms	Unidentified *Streptococcus*, *Pseudomonas aeruginosa*, *Klebsiella*, *Haemophilus influenzae*, *Candida albicans*, Plasmocoagulase-positive *Staphylococcus*	*Pneumocystis jiroveci*, *Salmonella*, *Acinetobacter anitratus*, *Candida albicans*, *Aspergillus*	Unidentified *Streptococcus*, *Haemophilus influenzae*, Plasmocoagulase-positive *Staphylococcus*, *Pseudomonas aeruginosa*, *Candida albicans*
Pulmonary sequelae	Bronchiectasis, pneumatocele	Bronchiectasis, multiple pneumatoceles	Multiple pneumatoceles
Other manifestations	Arthralgia and swelling of large and small joints, hyperlaxity	Hyperlaxity, failure to shed primary teeth	
Treatments	Occasional intramuscular gammaglobulin, antibiotic therapy according to infections	Intravenous immunoglobulin, antibiotic and antifungal prophylaxis	Antibiotic therapy of recurrent infections
STAT3 mutations	Not analyzed	c.1145 G>A p.382Arg>Gln	Analyzed in the sister and her daughter, some years later c.1397 A>G N p466Asn>Ser

Abbreviation: NIH, National Institutes of Health.
[a]As described in Ref. 6 (score>40 high suspicion)

Patient 3

A 3-year-old boy was diagnosed with HIES based on a clinical history of obstructive bronchitis, urethritis, pyodermatitis, and skin abscesses since the age of 10 months, with high IgE and IgG titers. The patient died from complications of chronic bullous lung disease at the age of 4 years.

His mother had died from chronic lung disease at the age of 40, although no definitive diagnosis was established. She had no history of asthma or smoking, and no hypogammaglobulinemia was detected. Plasma IgE levels were not tested. She could have had undiagnosed HIES.

The patient's sister was diagnosed with HIES at the age of 30. She had had recurrent respiratory infections (with isolation of *Staphylococcus aureus* on 1 occasion), bronchiectasis, moderate eczema, recurrent oral candidiasis, spontaneous rib fractures (radiographic finding), and osteoporosis. IgE values were 32 000 IU/mL, and a blood test showed hypereosinophilia. In 2007, a molecular diagnosis confirmed a mutation in *STAT3*. The second daughter of this patient (ie, the niece of Patient 3) was diagnosed with HIES at the age of 20 months based on family history, eczema since birth, occasional oral candidiasis, and 1 episode of respiratory tract infection. She also had the same mutation as her mother.

HIES is a very rare primary immunodeficiency, representing less than 2% of cases in the registry of the European Society for Immunodeficiencies (www.esid.org). It can present in childhood with heterogeneous clinical features and variable prognosis.

Clinical diagnosis can be difficult to establish in children, owing to similarities with other clinical entities, and a differential diagnosis between HIES and allergy in children with severe eczema and relatively high serum IgE levels is mandatory [3]. Neonatal rash could help to differentiate AD-HIES from AR-HIES. Genetic studies can confirm the diagnosis and enable close follow-up and prompt antibiotic and antifungal prophylaxis and, in selected cases, IVIG therapy. Furthermore, molecular diagnosis facilitates prenatal diagnosis and genetic counseling.

Clinical heterogeneity with the same mutation in the same family (Patient 3) is not uncommon in other primary immunodeficiencies [9] and probably reflects the role of other nonimmunological factors in the development of the disease.

Diminished counts of $CD4^+$ T lymphocytes secreting interleukin 17 (subtype 17 helper T cell [T_H17]) have been observed in *STAT3*-deficient patients, and a major role has been assigned to this subset [10]. However, the mechanisms underlying the pathological features of this disease have yet to be elucidated. Normal T_H17 values have not been defined in healthy young children, and T_H17 determinations are not yet widely available. The knowledge gained from further studies of this condition will help us to improve therapy and outcome.

Acknowledgments

We are very grateful to Dr C Woellner for the genetic studies and comments on the paper and to C O'Hara for the English language revision.

Different Patterns of Sensitization in Allergy to Dry Fermented Sausage

D González-de-Olano,[1] M Gandolfo-Cano,[1] E González-Mancebo,[1] A Meléndez-Baltanás,[1] R Juárez-Guerrero,[1] B Bartolomé[2]
[1]*Allergy Unit, Hospital de Fuenlabrada, Madrid, Spain*
[2]*Research & Development Department, Bial-Arístegui, Bilbao, Spain*

Key words: Allergy. Dry Fermented Sausage. Route of Sensitization.

Palabras clave: Alergia. Fuet. Ruta de sensibilización.

Table. Results of the Allergy Study in All 3 Patients

	Patient 1	Patient 2	Patient 3
Skin prick tests, mm			
– *Alternaria alternata*	7	0	0
– *Cladosporium herbarum*	5	0	0
– *Penicillium notatum*	4	10	4
– *Aspergillus fumigatus*	4	0	0
– *Candida albicans*	5	0	0
Pork meat	0	0	0
Spices[a]	Negative	Negative	Negative
Other inhalants[b]	Pollen/cat	Pollen	Negative
Prick-by-prick, mm			
Sausage outer skin	8	20	4
Sausage meat	0	0	0
P chrysogenum blanc spores	12	8	6
Additives:			
– Starter culture	0	0	0
– Fast fermenting culture	0	0	0
Mushroom	NP	17	NP
Cured cheese	NP	10	NP
Saline	0	0	0
Histamine	5	5	4
Specific IgE, kU_A/L			
– *Penicillium blanc*[c]	0.36	0.36	1.9
– *Alternaria alternata*	58.5	<0.35	<0.35
– *Cladosporium herbarum*	3.85	<0.35	<0.35
– *Penicillium notatum*	0.88	2.7	1.8
– *Aspergillus fumigatus*	1.98	<0.35	<0.35
– *Candida albicans*	3.54	<0.35	<0.35
Edible mushrooms			
– *Agaricus bisporus*	NP	1.2	NP
– *Boletus edulis*	NP	<0.35	NP
– *Pleurotus ostreatrus*	NP	<0.35	NP
Total IgE	192	47	28
IgE immunoblotting			
– IgE reactivity protein, kDa	55, 18	55, 21, 18	18

Abbreviations: Ig, immunoglobulin; NP, not performed.
[a]Including mustard, garlic, pepper, paprika, and oregano.
[b]Including grass pollen, dog and cat epithelium, dust mites, and storage dust mites.
[c]Extract obtained from the spores of *Penicillium chrysogenum blanc* used during the manufacture of dry sausage (provided by the manufacturer). Specific-IgE determinations against *P chrysogenum* extract were carried out using the enzyme allergosorbent test.

Manifestations of mold allergy are classically related to symptoms of asthma and other respiratory diseases; however, food allergy to molds is rare. It is common practice to add flavor-enhancing molds to traditional foods. Cases of allergy after ingestion of fermented food in patients sensitized to molds have been described occasionally [1,2].

We report on 3 girls aged 15 years, 16 years, and 4 years (P1, P2, and P3, respectively) with a history of labial angioedema and oropharyngeal pruritus after eating a cured, dry Catalonian sausage of pork meat in a pork gut fermented with *Penicillium chrysogenum blanc*. None of the patients presented any symptoms after ingestion of pork meat or spices. Patient 2 had also presented adverse reactions to mushrooms and cured cheese since childhood and had pruritus with a wheal and flare reaction when passing close to a charcuterie. Two of the patients (P1 and P2) had presented perennial asthma since childhood. P3 had never presented allergic symptoms.

The *Penicillium chrysogenum* samples used in the preparation of the sausage, namely, *P chrysogenum blanc*, starter culture, and fast fermenting culture, were provided by the manufacturer. *P chrysogenum blanc* protein extracts (PCE) were prepared by homogenization in phosphate-buffered saline, dialyzation, and lyophilization. Skin prick tests to commercial extracts from common inhalants, spices, pork meat, and

PCE extract were performed with positive results (wheal ≥3mm) to all the commercial molds and to PCE for P1, and PCE only for P2 and P3 (Table). Prick-by-prick tests with the sausage skin, sausage meat, and additives used during manufacture only showed a positive result to outer sausage skin and to spores of *P chrysogenum blanc* in the 3 patients. Serum specific immunoglobulin (Ig) E against commercial mold extracts (Pharmacia® CAP system) were >0.35 kU_A/L for all the molds tested in P1 and only for *P chrysogenum* in P2 and P3. Specific-IgE determinations against PCE carried out using the enzyme allergosorbent test disclosed 0.36 kU_A/L for P1 and P2 and 1.9 kU_A/L for P3. *P chrysogenum blanc* extract was analyzed by sodium dodecyl-polyacrylamide gel electrophoresis (SDS-PAGE) as described by Laemmli [3], showing protein bands ranging between 80 and 12 kDa. SDS-PAGE revealed IgE reactivity with proteins of 55 and 18 kDa for P1, proteins of 55, 21, and 18 kDa for P2, and an 18-kDa protein band for P3 (Table).

P chrysogenum, also known as *Penicillium notatum*, is a widely distributed heterotrophic organism, since its characteristics allow it to live in multiple habitats (in indoor environments or growing on foods), and is one of the main causes of allergy. The symptoms of mold allergy usually affect the respiratory tract [4]; however, as *P chrysogenum* is frequently a contaminant of foods, beverages, and drugs, patients can also be exposed via the oral route [5].

We report 3 cases of allergy to a dry fermented sausage with *P chrysogenum blanc*. An IgE-mediated mechanism was demonstrated in all 3 cases, but the IgE-reactivity bands were different in each. Patients with respiratory and digestive symptoms (P1 and P2) were sensitized to proteins of 55 and 18 kDa, while the patient with digestive symptoms (P3) was sensitized to an 18-kDa protein. A comparison using databases revealed that none of these proteins have been reported as food allergens [6]. The authors hypothesize that sensitization to different allergens might induce different symptoms. Nevertheless, further evaluation is necessary. Physicians should remember that the ingestion of aeorallergenic molds in food may induce allergic reactions regardless of previous related respiratory symptoms.
